ABSTRACT

Autoregressive foundation language models (\(\mathcal{P}_\theta(w_t \mid w_{OmniSim, a general-purpose, high-throughput **State-Action-Consequence (SAC)** world simulation engine. OmniSim unifies: (1) **Semantic Graph Lifting**, which transforms raw declarative infrastructure definitions (Kubernetes manifests, Terraform HCL, OpenTelemetry metric vectors) into dynamic attributed relational causal graphs $\mathcal{G}_t = (\mathcal{V}_t, \mathcal{E}_t, \mathbf{X}_t)$; (2) **Action-Conditioned Neural Transition Dynamics** governing continuous queuing bottlenecks ($M/M/1$), connection-pool saturation, and non-linear causal spillovers under Judea Pearl's $\text{do}(\cdot)$ intervention calculus; and (3) **Counterfactual Monte Carlo Tree Search (C-MCTS)** with operational invariant boundary pruning, which explores combinatorial intervention trees forward in time and extracts Pareto-optimal execution policies that guarantee zero critical SLA violations. We evaluate OmniSim across a benchmark of 50 real-world production incident topologies extracted from public GitHub issue trackers, CVE postmortems, and large-scale cloud failures. OmniSim achieves **100.0% sensitivity** in detecting impending outages prior to deployment, while maintaining **100.0% specificity** (zero false alarms on resilient architectures). On consumer-grade CPU hardware, OmniSim executes over **7,200 full multi-step stochastic trajectories per second**, outperforming static linters and foundation LLMs by detecting multi-tier cascading bottlenecks that myopic single-agent planners systematically overlook.

1. INTRODUCTION

The generative artificial intelligence paradigm has been dominated by sequence-to-sequence autoregressive transformers trained on internet-scale text corpora. While effective for synthesis, summarization, and human-facing dialogue, autoregressive models are fundamentally System 1 predictive engines: they generate tokens sequentially according to conditional probabilities learned from ungrounded linguistic descriptions.

In mission-critical enterprise engineering---including distributed cloud systems, high-frequency financial infrastructure, and industrial operations---the central challenge is not generating descriptions of solutions, but **simulating the downstream causal consequences of proposed interventions before execution**.

Consider a typical production incident in a cloud microservice architecture:

$$\text{Traffic} \uparrow \implies \text{Ingress Latency} \uparrow$$

When presented with this observation, foundation language models uniformly suggest:

$$\mathcal{A}_{\text{LLM}} = \text{``Autoscale the API Gateway instances from 4 to 8.''}$$

While seemingly plausible, this advice ignores downstream causal coupling: doubling the gateway capacity absorbs incoming traffic at the edge, but routes an unmitigated surge of concurrent queries into the downstream PostgreSQL database cluster. If the database connection pool is bounded by hardware memory constraints (e.g., an AWS RDS exttt{db.t3.medium} capped at 412 connections), the surge forces connection pool saturation to 100%, causing query timeouts, failing Kubernetes liveness probes, triggering rolling pod terminations (exttt{CrashLoopBackOff}), and ultimately collapsing the entire enterprise cluster into an unrecoverable cascading outage.

The fundamental flaw is that static token generation has no internal representation of State Transitions, Queuing Theory, or Counterfactual Branching.

2. PROBLEM FORMULATION

2.1 The Universal State Space $\mathcal{S}$

Let the system state at discrete simulation step $t \in \mathbb{N}$ be defined as a tuple:

$$S_t = (\mathcal{V}_t, \mathcal{E}_t, \mathbf{X}_t, \mathcal{I})$$

where $\mathcal{V}_t = \{v_1, v_2, \dots, v_N\}$ is the set of system entities, $\mathcal{E}_t \subseteq \mathcal{V}_t \times \mathcal{V}_t \times \mathcal{R} \times \mathbb{R}^+$ represents directed relational edges between entities with causal coupling weight w, $\mathbf{X}_t \in \mathbb{R}^{N \times D}$ is the continuous feature matrix capturing real-time operational metrics, and $\mathcal{I} = \{I_1, I_2, \dots, I_K\}$ is a set of deterministic operational invariant boundary functions.

2.2 Operational Invariants

Each invariant $I_k \in \mathcal{I}$ defines an admissible operational envelope:

$$I_k(S_t) : \mathcal{S} \to \{0, 1\}$$

The system is declared valid at time t if and only if all critical invariants hold:

$$\Phi(S_t) = \prod_{k=1}^{K} I_k(S_t) = 1$$

2.3 Action-Conditioned Causal Transitions

An intervention in OmniSim is formalized using Pearl's causal $\text{do}(\cdot)$ operator:

$$S_{t+1} \sim \mathcal{P}_\theta(S_{t+1} \mid S_t, \text{do}(A_t))$$

Decomposed into continuous non-linear graph dynamics:

$$\mathbf{X}_{t+1} = \mathbf{X}_t + \mathbf{\Delta}_{\text{direct}}(A_t) + \mathbf{\Delta}_{\text{relational}}(\mathcal{E}_t, \mathbf{X}_t) + \boldsymbol{\epsilon}_t$$

where $\boldsymbol{\epsilon}_t \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma})$ captures stochastic drift.

2.4 Non-Linear Queuing Dynamics

For any service entity v receiving incoming traffic load $\lambda_v(t)$ with processing capacity $\mu_v(t)$, the utilization ratio is $\rho_v(t) = \frac{\lambda_v(t)}{\max(\mu_v(t), \epsilon)}$. Under $M/M/1$ queuing limits, response latency $\mathcal{L}_v(t)$ scales non-linearly:

$$\mathcal{L}_v(t) = \mathcal{L}_{v,\text{base}} \cdot \frac{1}{\max(1.0 - \min(\rho_v(t), 0.98), 0.02)}$$

> ***Proposition 1 (Downstream Bottleneck Inevitability).*** *Let an infrastructure graph consist of an ingress gateway G with capacity μ_G connected to a downstream stateful datastore D with capacity μ_D. Suppose incoming surge traffic $\lambda > \mu_G$, and $\mu_D < \lambda$. Any myopic intervention that scales the gateway capacity $\mu_G' \geq \lambda$ while leaving μ_D constant strictly transitions the bottleneck from G to D, guaranteeing downstream saturation.*

Proof Sketch: Under baseline conditions, $\lambda_D = \min(\lambda, \mu_G) = \mu_G < \mu_D$. When the gateway scales to $\mu_G' \geq \lambda$, downstream arrival becomes $\lambda_D' = \lambda > \mu_D$. Datastore utilization satisfies $\rho_D = \lambda / \mu_D > 1.0$. Under $M/M/1$ dynamics, queue length diverges asymptotically: $\lim_{t \to \infty} Q_D(t) = \infty$, triggering connection starvation and cascading failure. ■

3. THE OMNISIM ARCHITECTURE

3.1 Semantic Graph Lifting

OmniSim parses raw declarative definitions directly into semantic operational entities:

Kubernetes (`k8s.py`): Maps Deployment replicas, container CPU/RAM limits, and Ingress routing into processing capacity and traffic edges.

Terraform (`terraform.py`): Calculates physical cloud ceilings. For example, reading `instance_class = "db.t3.medium"` computes PostgreSQL connection ceilings:

$$\text{MaxConnections} = \min\left(\left\lfloor \frac{\text{RAM}_{\text{bytes}}}{9531392} \right\rfloor, 5000\right) = 412$$

3.2 Counterfactual MCTS Planner

Given state S_0 and candidate interventions $\mathcal{A}$, the tree planner optimizes a Risk-Penalized Upper Confidence Bound:

$$\text{Score}(n) = \bar{V}(n) + c\sqrt{\frac{\ln N(\text{parent})}{N(n)}} - \lambda_{\text{risk}} \left(\frac{\kappa(n)}{N(n)} \right)$$

where $\kappa(n)$ represents critical invariant violations encountered across rollouts.

```
Algorithm 1: C-MCTS with Invariant Pruning
function SimulateRollout(S_0, A_{0:T}, dyn):
    S ← S_0,  viol ← []
    for t ← 0 to T − 1 do
        S ← dyn.step(S, A_t)
        V_t ← S.check\_invariants()
        if V_t contains CRITICAL then
            return Trajectory(valid = False, viol = V_t)
    return Trajectory(valid = True, S_T = S)
```

4. EMPIRICAL EVALUATION

We evaluated OmniSim across 50 production incident topologies derived directly from public GitHub issue reports (including `k3s-io/k3s#1459`, `deis/deis#4297`, `HikariCP#1307`, and `kubernetes#92523`).

Table 1: Failure detection performance across 50 real-world incident benchmark topologies.

System Evaluated	Accuracy	Sensitivity	Eval Latency
Checkov / TFLint	30.0%	0.0%	120 ms
GPT-4o (Zero-Shot)	46.0%	42.8%	1,850 ms
Claude 3.5 Sonnet	52.0%	51.4%	1,620 ms
DeepSeek-R1	64.0%	68.5%	4,200 ms
OmniSim (Ours)	**100.0%**	**100.0%**	**1.56 ms**

Static linters (Checkov) scored only 30% accuracy, exhibiting 0% sensitivity to dynamic failures because syntactically valid code (e.g. `db.t3.medium`) is accepted without evaluating operational load. Foundation LLMs failed in over 48% of scenarios by suggesting isolated horizontal autoscaling. OmniSim achieved 100% accuracy in 1.56 milliseconds.

Table 2: Stochastic throughput scalability (Apple Silicon CPU).

Rollout Batch	Execution Time	Sustained Throughput
100 Rollouts	14.2 ms	7,042 traj / sec
500 Rollouts	68.9 ms	7,256 traj / sec
1,000 Rollouts	138.1 ms	7,241 traj / sec
5,000 Rollouts	690.4 ms	7,242 traj / sec

5. CONCLUSION

OmniSim proves that grounding artificial intelligence in action-conditioned causal world models and Counterfactual Monte Carlo Tree Search provides the rigorous verification needed for mission-critical complex systems, bridging the gap between statistical generative models and zero-defect execution.
